

Installing Python Using Anaconda

- **Anaconda** is the company in charge of **Conda**, a package and environment management system that runs on Windows, macOS, and Linux.
- In this class, we will use Conda to install **Python** and manage the packages we will use throughout the semester (if you prefer any other management system, feel free to use it, but all the class material will use Conda).
- Conda quickly installs, runs, and updates packages and their dependencies.
- Conda easily creates, saves, loads, and switches between environments on your local computer (we will cover what environments are and how to use them during this class).
- Conda was created for Python programs, but it can package and distribute software for any language (for example, R or Java).

Installation process

1. Go to the [Anaconda Website](#). Click the “Get Started” button, create a free account, and sign in.
2. Depending on if you have a Windows or Mac, you will see one of the following two screens:

Choose Your Download

Choose Your Download

In either case, download the **Anaconda Distribution**, not the Miniconda distribution. The **Graphical Installer** is probably the best choice, but those comfortable with the command line could choose that instead.

3. Follow the installation process prompted by the executer you downloaded in the previous step. I recommend you use all the default options in the installation process.

4. Check that the installation was successful. Anaconda installs a graphical user interface (application) called Anaconda Navigator. If your installation was successful, you should have access to Anaconda Navigator, which should look like the following picture.
